## About this Guide

---

webMethods Integration Server provides built-in services that let you build secure MIME messages, transport them over the Internet, and extract information from MIME messages that are passed into the pipeline.

This guide is for users who want to use Software AG Designer to:

- Construct MIME messages.
- Secure MIME messages by digitally signing and encrypting them.
- Extract information from MIME messages such as header fields and content, decrypting this information if necessary.
- Transport MIME messages over the Internet.

**Note:** This guide describes features and functionality that might or might not be available with your licensed version of webMethods Integration Server. For information about the licensed components for your installation, see the **Settings > License** page in the webMethods Integration Server Administrator.

## Document Conventions

---

Convention	Description
<b>Bold</b>	Identifies elements on a screen.
Narrowfont	Identifies storage locations for services on webMethods Integration Server, using the convention <i>folder.subfolder:service</i> .
UPPERCASE	Identifies keyboard keys. Keys you must press simultaneously are joined with a plus sign (+).
<i>Italic</i>	Identifies variables for which you must supply values specific to your own situation or environment. Identifies new terms the first time they occur in the text.
Monospace font	Identifies text you must type or messages displayed by the system.

---

Convention	Description
{ }	Indicates a set of choices from which you must choose one. Type only the information inside the curly braces. Do not type the { } symbols.
	Separates two mutually exclusive choices in a syntax line. Type one of these choices. Do not type the   symbol.
[ ]	Indicates one or more options. Type only the information inside the square brackets. Do not type the [ ] symbols.
...	Indicates that you can type multiple options of the same type. Type only the information. Do not type the ellipsis (...).

---

## Documentation Installation

---

You can download the product documentation using the Software AG Installer. The documentation is downloaded to a central directory named `_documentation` in the main installation directory (SoftwareAG by default).

## Online Information

---

### Software AG Documentation Website

You can find documentation on the Software AG Documentation website at <http://documentation.softwareag.com>. The site requires Empower credentials. If you do not have Empower credentials, you must use the TECHcommunity website.

### Software AG Empower Product Support Website

You can find product information on the Software AG Empower Product Support website at <https://empower.softwareag.com>.

To submit feature/enhancement requests, get information about product availability, and download products and certified samples, go to [Products](#).

To get information about fixes and to read early warnings, technical papers, and knowledge base articles, go to the [Knowledge Center](#)

### Software AG TECHcommunity

You can find documentation and other technical information on the Software AG TECHcommunity website at <http://techcommunity.softwareag.com>. You can:

- 
- Access product documentation, if you have TECHcommunity credentials. If you do not, you will need to register and specify "Documentation" as an area of interest.
  - Access articles, demos, and tutorials.
  - Use the online discussion forums, moderated by Software AG professionals, to ask questions, discuss best practices, and learn how other customers are using Software AG technology.
  - Link to external websites that discuss open standards and web technology.

# 1 Overview of MIME and S/MIME Messages

---

■ Overview .....	10
■ What Is MIME? .....	10
■ What Is S/MIME? .....	14
■ The MIME and S/MIME Services .....	19
■ MIME Messages, MIME Entities, and MIME Objects .....	20

## Overview

---

This chapter explains what MIME and S/MIME message formats are and identifies their basic structures, describes how digital certificates and signatures work to identify the sender of a message, and explains how message encryption helps to ensure the privacy of a message.

## What Is MIME?

---

MIME (Multipurpose Internet Mail Extensions) is a standard yet flexible message format that is used to represent messages for transmission over the Internet. The MIME extensions were added to the Simple Mail Transport Protocol (SMTP) to allow e-mail transmissions to carry more than simple, 7-bit, textual messages.

The MIME standards allow for the transmission of:

- Non-textual content such as images, audio clips, and other binary files
- Messages in character sets other than US-ASCII
- Multiple files in a single transmission

Although originally developed for the SMTP protocol, MIME can be used by other Internet technologies (such as HTTP) as a standard messaging format.

## Basic Structure of a MIME Message

Like a standard mail message, a MIME message has two basic components: a set of *header fields* and a *body*.

## A simple MIME message

## Header Fields

Header fields provide information about the structure and encoding of a message. They consist of *name:value* pairs and appear at the top of the message. A MIME-compliant message must contain the "MIME-Version" header field.

Besides the MIME-Version header field, most messages have additional fields that supply information to the agent, transport, or application that will convey or consume the message. For example, when a MIME message carries anything other than plain, US-ASCII text, it must include the "Content-Type" header field. Messages that are routed over SMTP will also have the "Date," "To," and "From" header fields.

A message may also contain custom header fields that are specific to a particular agent or application. Such application-specific header fields must be prefixed with the characters "X-" to distinguish them from the standard header fields defined by the MIME and/or transport protocols.

This chapter does not attempt to describe the purpose or use of individual header fields. However, to use MIME effectively, you will need to understand which header fields your solution requires and know how to set them or interpret them correctly. For information about header fields, see the following references.

## The Body

The body of a MIME message contains the actual content of the message. It is separated from the last header field by a blank line: a two-byte sequence consisting of an ASCII carriage return (CR) and an ASCII linefeed (LF) on a line by itself.

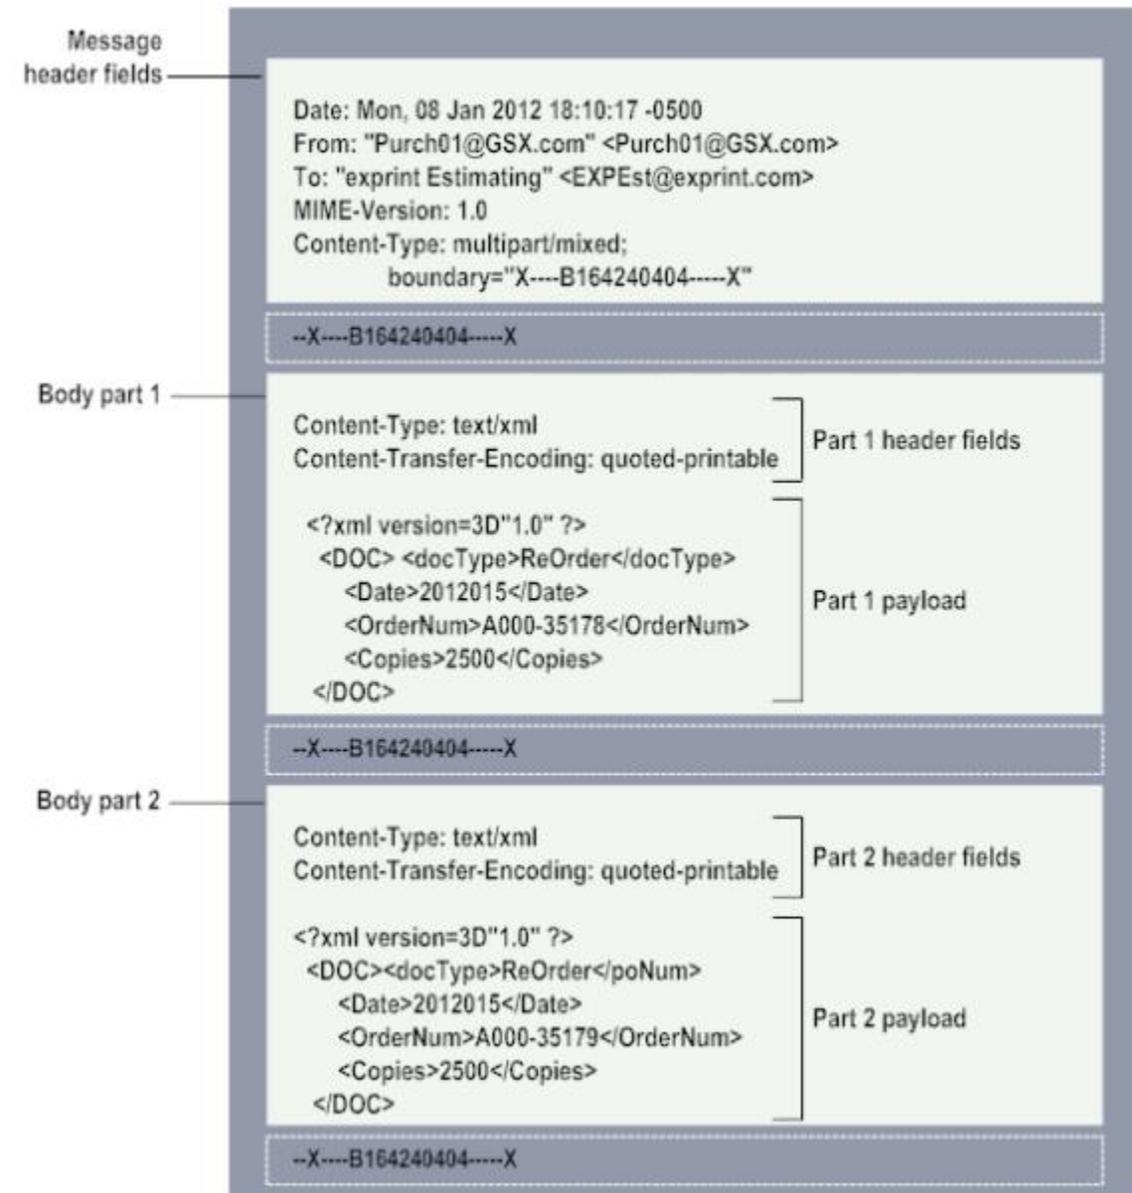

The message body can contain any sequence of data, including additional MIME messages. It is sometimes referred to as the *payload*. When you send an e-mail message, the body of your letter resides in the body of a MIME message. Similarly, when you attach a file to an e-mail message, the content of the file is carried in the body of a MIME message.

## Multipart MIME Messages

One of the key reasons for the development of MIME was to allow the transmission of multiple files (payloads) in a single message. When a MIME message contains multiple payloads, it has two kinds of header fields: *message headers*, which appear only at the beginning of the message, and *part headers*, which appear at the beginning of each body part.

Message headers apply to the entire message. Part headers apply only to the body part in which they appear. The following example shows a MIME message with two body parts.

## A multipart MIME message

If a MIME message has more than one payload, its Content-Type header field must be set to a *multipart* content type (for example, `Content-Type:multipart/mixed` or `Content-Type:multipart/alternative`), and it must declare a boundary separator. The boundary separator is a string that delimits body parts. It must appear before and after each part in the message. (In the example above, the string `X----B164240404-----X` is the boundary separator.)

**Note:** You may have noticed that the string separating the body parts in the preceding example includes a few extra characters that are not part of the separator string declared in the Content-Type header field. This is because the MIME format requires that two

dash characters precede each separator in the message and two dash characters follow the last separator string in the message.

When you build a multipart message with webMethods Integration Server, it automatically sets the Content-Type header to “multipart,” declares the separator string, and inserts the boundary separators for you.

## What Is S/MIME?

S/MIME (Secure Multipurpose Internet Mail Extensions) is a standard message format that allows MIME messages to be exchanged securely between parties over the Internet. It provides two security mechanisms—*digital signatures* and *encryption*—based on RSA technology and the Public Key Infrastructure (PKI).

## Digital Certificates

PKI employs a system of credentials known as digital certificates, or electronic documents that represent and identify individual users. A digital certificate is like an electronic identification card. It positively identifies a particular individual, organization, or application.

Besides providing information about the owner of the certificate (name, organization, e-mail address, and so forth), a digital certificate holds the owner’s public key. Under public/private key technology, a certificate owner has two keys. Parties that want to exchange messages securely with the certificate owner use the *public key* published on the owner’s certificate. Transmissions secured with a public key can only be successfully processed with the corresponding *private key*—a secret key that only the certificate owner has.

Digital certificates are issued and signed by Certificate Authorities (CAs). A CA is similar to a notary public. Its signature vouches for the identity of the individual or organization named on the certificate and attests to the validity of the public key. It also “seals” the certificate with a digital signature, which certifies the certificate’s contents and prevents it from ever being altered undetected. VeriSign and Entrust are examples of public CAs. They are considered “root-level” entities. Other intermediaries, such as financial institutions, are also permitted to issue certificates under the authority of a root CA.

You cannot verify the authenticity of a certificate without having the certificate of the CA that issued it. If the issuing CA is an intermediary, you must also have the certificate of its CA. The set of certificates required to trace the authenticity of a certificate back to a trusted CA is called a *certificate chain*.

**Note:** To authenticate a certificate, some recipients require a *complete* certificate chain—one that extends all the way back to a root-level CA—while others are satisfied with a partial chain that goes back to a specific intermediary. Always submit a complete chain unless you know for certain that the recipient accepts partial chains.

## Digital Signatures

A digital signature is a special block of data affixed to a message that assures the identity of the sender and the integrity of the message.

A digital signature secures a message in several ways. First, it contains the sender's digital certificate. This allows a recipient to identify the sender and determine whether the sender is a trusted and authorized party. In this way, digital signatures support the identification and authorization processes.

Second, a digital signature assures a recipient that the owner of the enclosed certificate sent the message. A digital signature is produced using the sender's private key. If a recipient can successfully "decode" the signature with the public key from the sender's certificate, the recipient is positively assured that the message is from the person or organization identified on that certificate. This characteristic provides both authentication (the sending party is who it claims to be) and nonrepudiation (the sending party cannot deny issuing the message).

Finally, a digital signature assures the integrity of the message with a *message digest* — a hash code that is mathematically derived from the message itself. When a recipient opens a signed message, it recalculates the hash code and compares its result to the original hash code in the signature. If the values don't match, the recipient knows that the message was deliberately or inadvertently altered after it was signed.

## Explicit and Implicit Signatures

There are two types of digital signatures: *explicit signatures* and *implicit signatures*.

An explicit signature is appended as a separate body part to the end of a MIME message. This format is sometimes referred to as the *clear-signing* or *detached-signature* format. When a MIME entity contains an explicitly signed message, its Content-Type header field is set to "multipart/signed." This field also specifies the protocol and message-integrity algorithm (micalg) used to produce the signature.

Integration Server uses the "pkcs7-signature" protocol and the "SHA-1" integrity algorithm.

**Note:** Integration Server automatically sets the Content-Type header field when you sign a message using the S/MIME services. Your service does not need to do this.

The following is an example of an explicitly signed MIME message. Notice that the message has two body parts: the first part contains the payload; the second part contains the signature.

## An explicitly signed message

This content-type indicates that the message is explicitly signed

```

--X----B164240404-----X
```

A message can also be implicitly signed. When you use this technique, the message is encoded within the signature block, thus preventing the message from being extracted or read unless the signature is processed by a PKCS-enabled recipient. For this reason, explicit signatures are preferred because they also make the message available to non-PKCS recipients.

When a MIME entity contains an implicitly signed message, its Content-Type header field is set to "application/pkcs7-mime."

The following is an example of a text message that has been implicitly signed. As you can see, the text of the message is not visible.

### An implicitly signed message

This content-type indicates that the message is implicitly signed

```
Date: Mon, 08 Jan 2012 10:35:23 -0500
From: "Exprint Estimating" <EXPEst@exprint.com>
To: "Purch01@GSX.com" Purch01@GSX.com
MIME-Version: 1.0
Message-ID: <36898002,DBDJ8097@exprint.com>
Content-Type: application/pkcs7-mime; smime-type=signed-data;
              name=smime.p7m
Content-Transfer-Encoding: base64
Content-Disposition: attachment; filename=smime.p7m
```

The payload contains the signature, which carries an encoded form of the message.

## Encryption

Encryption is a way to ensure privacy by assuring that a message can be read only by the intended recipient.

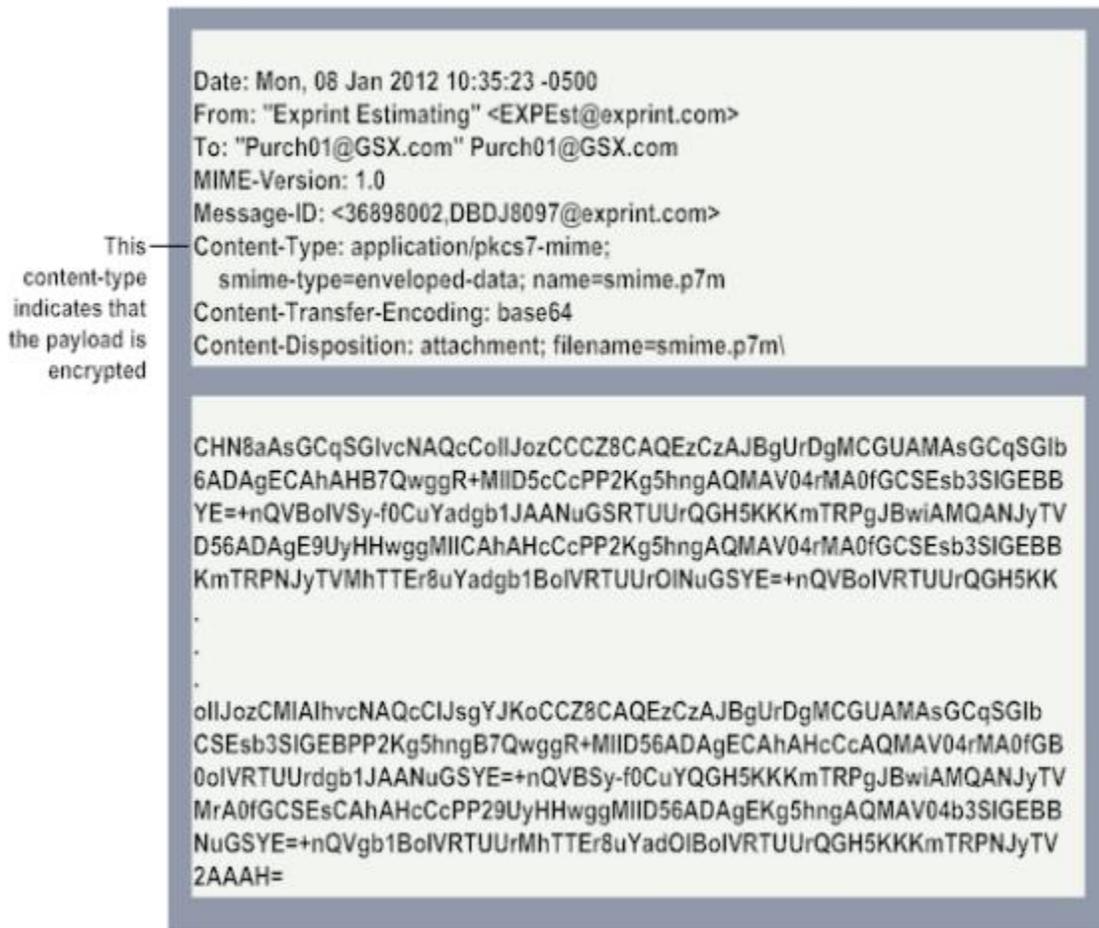

Encryption is performed using a pair of keys. The sending party encrypts the message using the recipient's public key. The recipient decrypts the message with its private key. Since the owner of the public key is the only one in possession of the private key, only the owner can successfully decrypt the message.

Integration Server supports RC2, TripleDES, and DES encryption algorithms. RC2 lets you specify a key length of 40, 64, or 128. TripleDES uses a key length of 192. DES uses a key length of 64 (in US versions of the product) or 40 (in non-US versions of the product).

The following is an example of an encrypted message. Note that its Content-Type header field is set to “application/pkcs7-mime” (required for encrypted messages) and that the payload contains the encrypted message.

**Note:** Integration Server automatically sets the Content-Type header field to the appropriate value when you encrypt a MIME message using the S/MIME services. Your service does not need to do this.

### An encrypted message

**Note:** Although encryption protects a message from being read by an unintended party, it does not assure message integrity, nor does it provide authentication or nonrepudiation. These qualities are guaranteed by digital signatures.

To encrypt a message, you must have the intended recipient’s certificate because it contains the public key you use to perform the encryption.

Most sites simply contact the parties with whom they want to exchange encrypted messages and request copies of their certificates (the other parties might e-mail their

certificates to you, for example). Then, they store the certificates in their file system, a database, or a special repository for security information.

It does not make any difference where you maintain the certificates of the parties with whom you want to exchange encrypted messages, as long as the certificates are in X.509 format and can be retrieved by Integration Server at run time.

## The MIME and S/MIME Services

The MIME and S/MIME services allow you to build secure MIME objects that you can send over the Internet. They also allow you to extract information from MIME messages that are placed in the pipeline, decrypting that information when necessary.

### Services Used to Construct MIME and S/MIME Messages

The following table lists services that you use to create MIME messages and optionally secure them using a digital signature and/or encryption. For information about how you use these services to create various kinds of MIME messages, see ["Building MIME and S/MIME Messages" on page 21](#).

Service	Description
<code>createMimeData</code>	Creates an empty MIME object, which you use to compose a MIME message.
<code>addMimeHeader</code>	Adds one or more header fields to a MIME object.
<code>addBodyPart</code>	Adds a body part (headers and content) to a specified MIME object.
<code>getEnvelopeStream</code>	Generates a MIME message from a MIME object.
<code>createSignedData</code>	Digitally signs a MIME message.
<code>createEncryptedData</code>	Encrypts a MIME message.
<code>createSignedAndEncryptedData</code>	Digitally signs a MIME message and then encrypts it.

### Services Used to Extract Data from MIME and S/MIME Messages

The following table lists services that you use to extract data from a MIME message. For information about how you use these services to decrypt, authenticate, and extract

information from a MIME message, see ["Extracting Data from MIME and S/MIME Messages" on page 41](#).

<b>Service</b>	<b>Description</b>
<code>createMimeData</code>	Produces a MIME object from a MIME message stream.
<code>getMimeHeader</code>	Retrieves the header fields from a MIME object.
<code>getContentType</code>	Retrieves the value of the Content-Type header field from a MIME object.
<code>getNumParts</code>	Reports the number of body parts in a MIME object.
<code>getBodyPartContent</code>	Retrieves the content from a specified body part in a MIME object.
<code>getBodyPartHeader</code>	Retrieves the header fields from a specified body part in a MIME object.
<code>processEncryptedData</code>	Decrypts the contents of an S/MIME object.
<code>processSignedData</code>	Authenticates the digitally signed contents of a specified S/MIME object.

## **MIME Messages, MIME Entities, and MIME Objects**

---

In this book, the term *MIME message* refers to a complete, top-level MIME message that is made up of a set of message header fields (including the mandatory MIME Version header) and a body.

The term *MIME entity* refers to any block of data composed of header fields and a body. It can mean either a complete MIME message or a single body part within a multipart message.

Most MIME services provided by Integration Server do not operate directly on a MIME message or a MIME entity. Instead, they operate on a *MIME object*. A MIME object is a parsed representation of a MIME message that allows webMethods services to add and/or retrieve the message's constituent elements (header fields and content). By convention, the variable that holds a MIME object is called *mimeData*.

## 2 Building MIME and S/MIME Messages

---

■ Overview .....	22
■ Creating a MIME Message .....	23
■ Signing a MIME Message .....	31
■ Encrypting a MIME Message .....	34
■ Signing and Encrypting a MIME Message .....	37

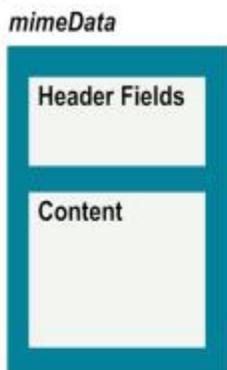

## Overview

To construct a MIME message with Software AG, you first create an “empty” MIME object and then populate the object with the appropriate header fields and content. After putting the required data into the MIME object, you generate a MIME message from the MIME object.

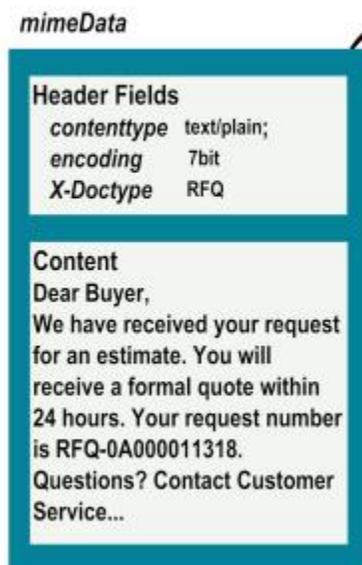

The following diagram illustrates this process.

### Constructing a MIME message

#### 1 Create an empty MIME object...

#### 2 ...Populate the MIME object with header fields and content...

#### 3 ...Generate a MIME message from the fully populated MIME object.

After you create a MIME message, you can digitally sign it—to identify that the message is being sent by a trusted source—and/or encrypt it.

## Creating a MIME Message

To create a MIME message, you use services from the `pub.mime` folder to create an empty MIME object, populate the MIME object with header fields and content, and generate the finished MIME message.

**Important:** The MIME object is an `IData` object whose contents you can examine during testing and debugging. However, the internal structure of this object is subject to change in future versions of `webMethods`. *Do not* explicitly set or map data to the elements in the MIME object with the pipeline editor. To add content to a MIME object, you must use *only* the MIME services that Integration Server provides for that purpose.

## How to Create a MIME Message

The following procedure describes the general steps you take to create a MIME message.

1. **Create an empty MIME object using `pub.mime:createMimeData`.** You do not need to pass any input parameters to this service.

This service returns an empty MIME object named `mimeData`.

2. **Add application-specific message headers with `pub.mime:addMimeHeader`.** If your message requires application-specific (for example, “X- type” fields) or transport-specific message headers (for example, “To” and “From” header fields), use `addMimeHeader` to specify them. This service takes as input a document called `mimeHeader`, whose fields and values specify message header field names and values.

For example, this `mimeHeader` document...

Name	Values
To	"xprint mEstimating" <EXPEst@exprint.com>
From	"Purch01@GSX.com" <Purch01@GSX.com>
X-Doctype	RFQ
X-Severity	5

...would produce the following message header fields:

```
To: "xprint Estimating" <EXPEst@exprint.com>
From: "Purch01@GSX.com" <Purch01@GSX.com>
X-Doctype: RFQ
X-Severity: 5
```

Note that you *do not* need to explicitly set the following message headers:

Message-ID  
MIME-Version

These headers are automatically generated by the service that produces the finished MIME message. If you explicitly set these fields in *mimeHeader*, they will be overwritten when the MIME message is generated.

You may set message headers before or after adding content (performing the next step 3, below). Either order is permitted, as long as you set them before you generate the finished MIME message.

**Tip:** Instead of using `addMimeHeader` to add message headers, you may alternatively pass a *mimeHeader* document to `createMimeData` when you create the MIME object.

Besides a *mimeHeader* document, you must pass to `addMimeHeader` the *mimeData* object produced in the previous step 1.

The `addMimeHeader` service does not return an output value. It simply updates the *mimeData* object that you pass to it.

- 3. Add one or more body parts with the `pub.mime:addBodyPart` service.** This service adds a single body part (both header fields and content) to the MIME object. To add multiple body parts, execute `addBodyPart` once for each part that you want to add. In the finished message, body parts appear in the order in which you add them—the first body part you add will be the first body part in the message.

Besides the *mimeData* object that you produced in step 1, `addBodyPart` takes three other parameters: *content*, *contentType*, and *encoding*.

- *content* is an `InputStream` containing the message content (the payload). Before invoking `addBodyPart`, your solution must acquire or generate this content and place it in the pipeline as an `InputStream`.

The way in which you acquire the content of your message depends on your particular solution. For example, you might acquire it from a file or from a back-end system or manufacture it with a custom-built service. Regardless of how you acquire your content, keep the following points in mind:

- Your content must exist as an `InputStream` in the pipeline. If it exists in some other form—for example, a `String` or a `byte[]`—you must convert it to an `InputStream` before adding it to the MIME object.
- The `InputStream` should contain only the body of the message (the payload). Do not put header fields in the `InputStream`. To specify header fields, use the *contentType*, *encoding*, *description*, and *mimeHeader* input parameters.

**Note:** If your `InputStream` already contains header fields, you can set the *isEnvStream* parameter to “true” to tell `addBodyPart` to pull the header fields out of the `InputStream` before adding it to the MIME object. For additional information about using the *isEnvStream* parameter, see the `addBodyPart` description in the *webMethods Integration Server Built-In Services Reference*.

- Do not encode the content before adding it to the MIME object—simply add it in its original form. If you want to encode the content for transport, set the *encoding* parameter (see below).
- *contentType* is a String specifying the value of the entity's Content-Type header field. Besides type and subtype, be sure to include any parameters that the header field requires as shown in the following example:

```
text/plain;charset=UTF8
```

For a description of standard content types, see *RFC 2046—MIME Media Types* at <http://www.imc.org/rfc2046>.

Be aware that when you create a single-part message, the value you specify in *contentType* is assigned to the Content-Type header for the entire MIME message. In this case, *contentType* will override any value you may have previously set in *mimeHeader* (using the `addMimeHeader` service, for example.)

When you create a multipart message, the value you specify in *contentType* is assigned to the Content-Type header for the body part. The Content-Type header for the entire MIME message is automatically set to `multipart/mixed` (or to `multipart/subType` if the *subType* parameter was specified when the MIME object was created.)

- *encoding* is a String specifying the value of the entity's Content-Transfer-Encoding header field. This field also specifies the scheme in which you want the entity's content encoded. If you set *encoding* to "base64," for example, the `getEnvelopeStream` service will base64-encode the data in *content* when it generates the finished MIME message.

*encoding* must be one of the following values:

Value	Description
7bit	Specifies that <i>content</i> is 7-bit, line-oriented text that needs no encoding.  Use this value when <i>content</i> contains lines of 7-bit, US-ASCII text (no octets with decimal values greater than 127; no NULs).
8bit	Specifies that <i>content</i> is 8-bit, line-oriented text that needs no encoding.  Use this value when <i>content</i> contains lines of 8-bit text (octets with decimal values greater than 127; no NULs).

**Note:** This encoding value is not recommended for messages that will be transported via SMTP over the Internet, because intervening servers that cannot accommodate 8-bit text may

Value	Description
	alter your content. To safely transport 8-bit text, use quoted-printable encoding instead.
binary	<p>Specifies that <i>content</i> contains binary information that needs no encoding.</p> <p>Use this value when <i>content</i> contains an arbitrary sequence of octets (binary data).</p> <p><b>Note:</b> This encoding value is not recommended for messages that will be transported via SMTP over the Internet, because intervening servers that cannot accommodate binary data may alter your content. To safely transport binary data, use base64 encoding instead.</p>
quoted-printable	Specifies that <i>content</i> contains 7- or 8-bit, line-oriented text that you want to encode using the quoted printable encoding scheme.
base64	Specifies that <i>content</i> contains an arbitrary sequence of octets (binary data) that you want to encode using the base64 encoding scheme.
uuencode	Specifies that <i>content</i> contains an arbitrary sequence of octets that you want to encode using the uuencode encoding scheme.

Be aware that when you create a single-part message the value you specify in *encoding* is assigned to the Content-Transfer-Encoding header for the entire MIME message. This value will override any value you may have previously set in *mimeHeader* (using the `addMimeHeader` service, for example).

When you create a multipart message, the value you specify in *encoding* is assigned to the Content-Transfer-Encoding header for the body part. The Content-Transfer-Encoding header in *mimeHeader*, if present, specifies the encoding for the entire MIME message. If Content-Transfer-Encoding is not specified in *mimeHeader*, or if the specified value is not valid for a multipart message, this header defaults to 7bit encoding. (7bit, 8bit, and binary are the only encoding values valid for multipart messages.)

**Note:** Besides the *content*, *contenttype*, and *encoding*, parameters described above, the `addBodyPart` service has a few other optional parameters you can use. For information about these parameters, see the `addBodyPart` description in the *webMethods Integration Server Built-In Services Reference*.

The `addBodyPart` service does not return an output value. It simply updates the `mimeData` object that you pass to it.

4. **Generate the finished MIME message with the `pub.mime:getEnvelopeStream` service.** After you finish populating the MIME object, invoke `getEnvelopeStream` to generate a MIME message. This service takes the populated `mimeData` object and produces an `InputStream` called `envStream`, containing the finished MIME message.

When `getEnvelopeStream` generates a MIME message, it does the following:

- Generates the Message-ID, MIME-Version, Content-Type, and Content-Transfer-Encoding message headers and inserts them at the top of the message.
- Sets the Content-Type header to “multipart,” generates a boundary string, and inserts it between body parts if `mimeData` contains multiple body parts.

**Note:** If `mimeData` contains a single body part, `getEnvelopeStream` will, by default, create an ordinary, single-part message. Some solutions, however, want a “multipart” message even if the message contains only a single body part. If your solution requires this structure, you can use the `createMultipart` parameter to tell `getEnvelopeStream` to generate a multipart message regardless of the number of body parts it finds in `mimeData`.

- Encodes the content for each body part according to its `encoding` value.

## Example—Creating a Single-Part MIME Message

The following flow service creates a single-part MIME message that contains a simple text message.

### Flow service that creates a simple MIME message

Step	Description
------	-------------

- |   |  |
|---|--|
| 1 | This step creates an empty MIME object. It does not take any inputs. It puts an empty MIME object named <code>mimeData</code> in the pipeline. |
|---|--|

---

**Step**    **Description**

---

- 2      This step adds two application-specific message headers in the MIME object. If you view the pipeline, you will see that the *mimeHeader* input variable is set as follows:

<u>Name</u>	<u>Value</u>
<i>X-DocType</i>	alert
<i>X-Severity</i>	9

- 3      This step generates the content of the message. This example uses a custom Java service to convert a String containing the following text to an *InputStream*:

```
We were not able to process your request because the account
number you gave us has expired. Please correct the account number
and resubmit your request
```

In practice, you are more likely to acquire your content from a file, the network, or a back-end system.

- 4      This step adds the content produced by step 3 to the *mimeData* object. If you view the pipeline, you will note that the *stream* output variable from step 3 is linked to this step's *content* input variable. Because *content* contains a simple text message, the *contenttype* and *encoding* parameters are set as follows:

<u>Parameter</u>	<u>Value</u>
<i>contenttype</i>	text/plain;charset=UTF8
<i>encoding</i>	quoted-printable

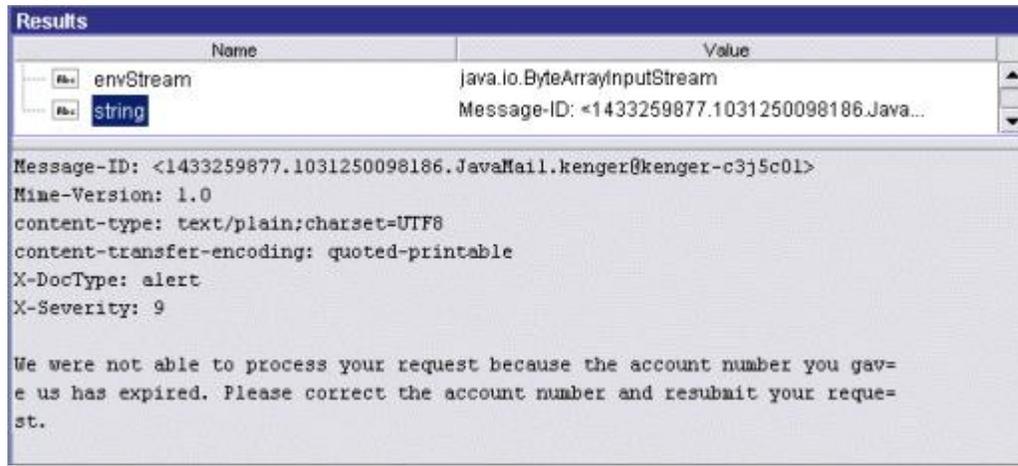

*isEnvStream* is set to "no" because the payload is not a MIME entity.

- 5      This step generates the finished MIME message. It takes the *mimeData* object that was populated in steps 2 and 4 and produces an *InputStream* called *envStream* that contains the MIME message. At this point, you could pass *envStream* to any process that expects a MIME message as input.

- 6      Because you cannot view an *InputStream*, this example includes a step that converts *envStream* to a String so you can examine the finished message with Designer. This technique is useful for testing and debugging.

If you examine the contents of *string* on the Service Result view, you will see a MIME message similar to the following:

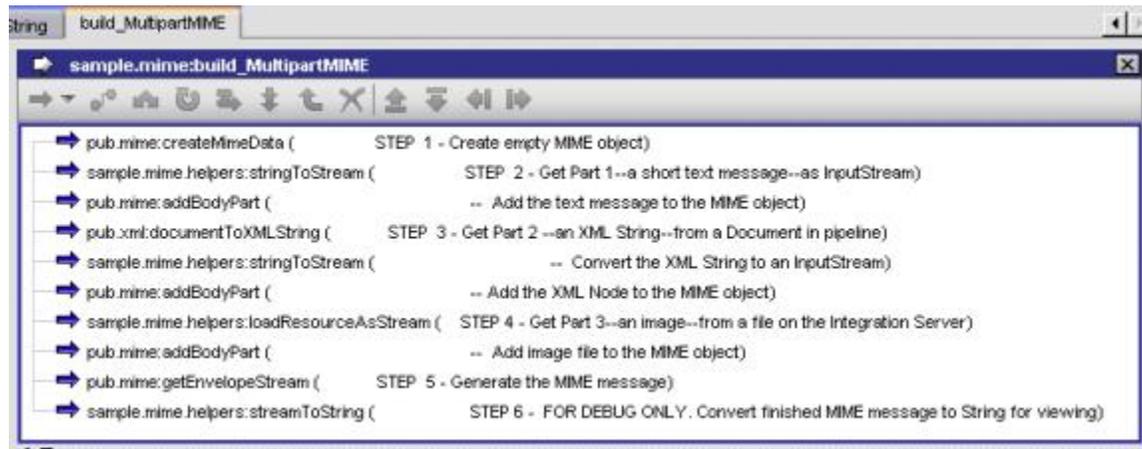

Step	Description
------	-------------

## Example—Creating a Multipart MIME Message

The following flow service creates a multipart MIME message that contains three parts: a simple text message, an XML document, and an image file. The steps you use to create a multipart message are essentially the same as the ones you use to create a single-part MIME message—the only difference is that you execute `addBodyPart` multiple times.

### Flow service that creates a multipart MIME message

Step	Description
------	-------------

- 1 This step creates an empty MIME object. It does not take any inputs. It puts an empty MIME object called *mimeData* in the pipeline.
- 2 This step generates the content of the message and adds it to the *mimeData* object. If you view the pipeline for the `addBodyPart` service in this step, you will

---

**Step**    **Description**

---

see that the *stream* output variable generated by the `stringToStream` service is linked to the *content* input variable. Because *content* contains a simple text message, the *contentType* and *encoding* parameters are set as follows:

Parameter	Value
<i>contentType</i>	text/plain;charset=UTF8
<i>encoding</i>	quoted-printable

- 3 This step creates an XML document from a document (IData object) in the pipeline, converts that XML document to an `InputStream`, and then adds the `InputStream` to the *mimeData* object. Because *content* contains an XML document, the *contentType* and *encoding* parameters are set as follows:

Parameter	Value
<i>contentType</i>	text/xml
<i>encoding</i>	quoted-printable

- 4 This step gets an image file from disk and adds it to the *mimeData* object. Because the file is retrieved as an `InputStream`, it can be linked directly to the *mimeData* object. In this case, *content* is an image file (binary data), so the *contentType* and *encoding* parameters are set as follows:

Parameter	Value
<i>contentType</i>	image/gif;name="b2b.gif"
<i>encoding</i>	base64

- 5 This step generates the finished MIME message. It takes the *mimeData* object populated in steps 2–4 and produces an `InputStream` called *envStream* that contains the multipart MIME message. At this point, you could pass *envStream* to any process that expects a MIME message as input.

- 6 Because you cannot view an `InputStream`, this example includes a step that converts *envStream* to a `String` so you can examine the finished message with Designer. This technique is useful for testing and debugging.

If you examine the contents of *string* on the Service Result view, you will see a MIME message similar to the following:

Step	Description
------	-------------

Results	
Name	Value
envStream	java.io.ByteArrayInputStream
string	Message-ID: <492789979.1031260238036.Java...

```

Message-ID: <492789979.1031260238036.JavaMail.kenger@kenger-c3j5c01>
Mime-Version: 1.0
Content-Type: multipart/mixed;
    boundary="-----_Part_0_39559387.1031260238016"

-----_Part_0_39559387.1031260238016
content-type: text/plain;charset=UTF8
content-transfer-encoding: quoted-printable

Print 2500 copies of attached image on 5x5 glossy 25lb stock. RUSH. Must h=
ave delivery by next Friday.
-----_Part_0_39559387.1031260238016
content-type: text/xml
content-transfer-encoding: quoted-printable

<?xml version=3D"1.0"?>
<PrintReq>

```

Points to keep in mind when building multipart MIME messages:

- By default, the Content-Type header field is set to “multipart/mixed.” If you want to use a different subtype, set the *subtype* parameter when you invoke `createMimeData`.
- Body parts appear in the message in the order in which you add them to the MIME object—the first part you add appears first in the message.
- If you set message headers (for example, using `addMimeHeader`) before you add body parts, those header fields will also be inserted into each body part. To prevent this, drop the *mimeType* variable from the pipeline before you perform an `addBodyPart` step or execute the `addMimeHeader` step after adding the message’s body parts.

## Signing a MIME Message

To digitally sign a MIME message you must have a keystore that contains the signer’s private key and an associated certificate chain. If you know that the recipient trusts an intermediate CA in your chain, the keystore can contain a partial chain that extends back to that CA. However, if you are not sure which CA the recipient trusts, the keystore should contain a complete chain.

**Note:** You are not required to have the signer’s certificate chain to sign a message; however, if you omit the chain, the recipient must produce the certificate chain when it receives the message. If you do not supply the signer’s certificate chain, and the recipient does not have a local copy of it, the signature verification process will fail. By

including the certificate chain with a signature, you ensure that the recipient will be able to process the signature.

## How to Create a Signed S/MIME Message

The following procedure describes the general steps you take to create a signed S/MIME message.

**Important:** If you want to create a signed and encrypted MIME message, use the special service that Integration Server provides for this purpose. For more information, see ["Signing and Encrypting a MIME Message" on page 37](#).

Before you begin, you must have a keystore alias and a password for at least one key alias. The credentials provided by the keystore alias and the key alias are used to sign the message. If you cannot locate these credentials or do not have direct access to them, consult your Integration Server Administrator.

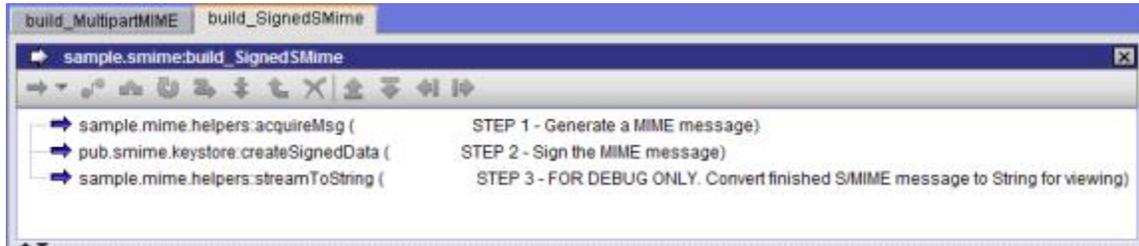

1. **Create an InputStream that contains the MIME message that you want to sign.** Use the procedure outlined in ["How to Create a MIME Message" on page 23](#) to create the MIME message.
2. **Pass your signing credentials to the `pub.smime.keystore:createSignedData` service.** This service takes an InputStream containing a MIME message and signs it using the private key and the certificates pointed by the keystore alias and key alias that you provide. It produces an InputStream containing the signed message.

## Example—Signing a MIME Message

The following flow service signs a single-part MIME message. To sign a MIME message, you must provide the alias of the keystore that contains the signing key, and the alias of the private key to use for signing. When you run the service from Designer, it will prompt you for the following:

Input Parameter	Description
<i>signersKeyStoreAlias</i>	<b>String</b> Alias of the keystore.
<i>signersKeyAlias</i>	<b>String</b> Alias of the private key of interest in the keystore.

## Flow service that signs a MIME message

Step	Description
------	-------------

- |   |  |
|---|--|
| 1 | This step creates a MIME message containing a simple text message. It produces an <code>InputStream</code> called <code>envStream</code> that contains the MIME message that will be signed.   |
| 2 | This step generates the signed MIME message. It takes the <code>InputStream</code> from step 1 and the credentials specified in <code>signersKeyStoreAlias</code> and <code>signersKeyAlias</code> and produces an <code>InputStream</code> called <code>SMimeEnvStream</code> that contains the signed message. |
| 3 | Because you cannot view the contents of an <code>InputStream</code> , this example includes a step that converts <code>SMimeEnvStream</code> to a <code>String</code> so you can examine the finished message with Designer. This technique is useful for testing and debugging.                                 |

If you examine the contents of `string` on the Service Result view, you will see a signed S/MIME message similar to the following. Note that this example creates an explicitly signed message—the message is in one body part and the digital signature is in another.

## Step Description

Results	
Name	Value
SMimeEnvStream	java.io.ByteArrayInputStream
string	Message-ID: <1192584370.1031261087878.Java...

```

## Encrypting a MIME Message

To encrypt a MIME message you must have the recipient's certificate. It contains the public key required to encrypt the message. To obtain this certificate, ask the parties with whom you want to exchange encrypted messages to send you their X.509 digital certificate in DER file format. For example, you might ask a party to e-mail the .DER file to you or transmit it in a special "certificates only" MIME message, which you can read using the `pub.smime:processCertsOnlyData` service.

After receiving the certificate, store it in a location (file system, database, or other repository) where it can be retrieved by Integration Server at run time. Once you have

access to the recipient's certificate, you can generate encrypted MIME messages that only the owner of the certificate can read.

## How to Create an Encrypted S/MIME Message

The following procedure describes the general steps you take to create an encrypted S/MIME message.

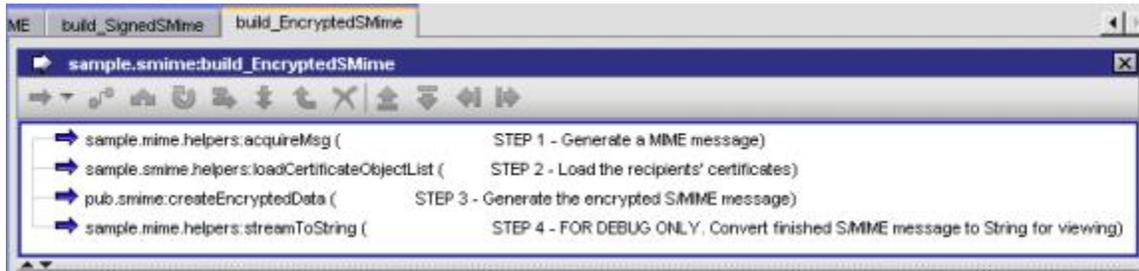

**Important:** If you want to create a signed and encrypted MIME message, use the special service that Integration Server provides for this purpose. For instructions, see ["Signing and Encrypting a MIME Message" on page 37](#).

1. **Create an InputStream containing the MIME message that you want to encrypt.** You can use the procedure outlined in ["How to Create a MIME Message" on page 23](#) to create the MIME message.
2. **Fetch the recipient's certificate as a byte[].** If the message will be sent to multiple recipients, fetch the certificate of each recipient. Load the certificates into a list (a one-dimensional array) of byte[] such that each element in the list holds the certificate of single recipient.
3. **Pass the certificate and the MIME message to the `pub.smime:createEncryptedData` service.** This service encrypts the InputStream containing the MIME message and produces a new InputStream containing the encrypted message.

## Example—Encrypting a MIME Message

The following flow service encrypts a MIME message. To run this example, you must have at least one certificate file. When you run this service from Designer, it will prompt you for the following:

Input Parameter	Description
<i>recipient1CertificateFile</i>	The name of the file containing the certificate of the first intended recipient, for example, <code>d:\netCerts\partner1cert.der</code> .
<i>recipient2CertificateFile</i>	The name of the file containing the certificate of the second intended recipient. If you want to encrypt the message for only one recipient, leave this input parameter empty.

Step	Description
------	-------------

- |   |  |
|---|--|
| 1 | This step creates a MIME message containing a simple text message. It produces an <code>InputStream</code> called <code>envStream</code> that contains the MIME message that will be encrypted.  |
| 2 | This step loads the recipient's certificates from the files specified in <code>recipient1CertificateFile</code> and <code>recipient2CertificateFile</code> . This example uses a custom Java service to perform this step. You will need to develop a similar mechanism to load the certificates of the parties to whom you want to send an encrypted message. |
| 3 | This step generates the encrypted MIME message using the <code>InputStream</code> from step 1 and the certificates from step 2. It produces a new <code>InputStream</code> called <code>SMimeEnvStream</code> that contains the encrypted message.   |
| 4 | Because you cannot view the contents of an <code>InputStream</code> , this example includes a step that converts <code>SMimeEnvStream</code> to a <code>String</code> so you can examine the finished message with Designer. This technique is useful for testing and debugging.   |

If you examine the contents of `string` on the Service Result view, you will see an encrypted S/MIME message similar to the one below.

Step	Description
------	-------------

Results	
Name	Value
SMimeEnvStream	java.io.ByteArrayInputStream
string	Message-ID: <525365981.1111585466499.JavaMail....

## Signing and Encrypting a MIME Message

If you want to sign and encrypt a message, you must use the special service, `pub.smime.keystore.createSignedAndEncryptedData`, that Integration Server provides for this purpose.

To use this service, you must provide the credentials for signing a message (the alias of the keystore and the signing key) and the credentials needed to encrypt a message (the recipient's certificate). For information about obtaining these credentials, see ["Signing a MIME Message"](#) on page 31 and ["Encrypting a MIME Message"](#) on page 34.

## Example—Signing and Encrypting a MIME Message

The following flow service signs and encrypts a MIME message. To run this example, you must provide the alias of the keystore that contains the signing key, and the alias of the private key to use for signing.

When you run this service from Designer, it will prompt you for the following:

Input Parameter	Description
<i>signersKeyStoreAlias</i>	<b>String</b> Alias of the keystore.
<i>signersKeyAlias</i>	<b>String</b> Alias of the private key of interest in the keystore.
<i>recipient1CertificateFile</i>	The name of the file containing the certificate of the first intended recipient, for example, d:\netCerts\partner1cert.der.
<i>recipient2CertificateFile</i>	The name of the file containing the certificate of the second intended recipient. If you want to encrypt the message for only one recipient, leave this input parameter empty.

Step	Description
1	This step creates a MIME message that contains a simple text message. It produces an <code>InputStream</code> called <i>envStream</i> , containing the MIME message that will be signed and encrypted.
2	This step generates the signed MIME message. It takes the <code>InputStream</code> from step 1 and the credentials specified in <i>signersKeyStoreAlias</i> and <i>signersKeyAlias</i> and produces an <code>InputStream</code> called <i>SMimeEnvStream</i> that contains the signed and encrypted message.
3	Because you cannot view the contents of an <code>InputStream</code> , this example includes a step that converts <i>SMimeEnvStream</i> to a <code>String</code> so you can examine the finished message with Designer. This technique is useful for testing and debugging.

Step	Description
------	-------------

If you examine the contents of *string* on the Service Result view, you will see an encrypted S/MIME message similar to the following:

Results	
Name	Value
abc encryptionAlg	DES
abc SMimeEnvStream	java.io.ByteArrayInputStream
abc string	Message-ID: <313144021.1111585993187.JavaMail.:

```

Message-ID: <313144021.1111585993187.JavaMail.user@user-d600>

■ Extracting Data from a Signed and Encrypted MIME Message .....	53

## Overview

Besides creating MIME messages, you can also use Integration Server services to extract information (header fields and/or content) from MIME messages that are placed in the pipeline. However, to gain access to the data within a MIME message, you must first convert that message to a MIME object. After you convert the message to a MIME object, you use services such as `getMimeHeader`, `getBodyPartContent`, and `getBodyPartHeader`, to retrieve the information within it.

The following diagram illustrates this process:

## Extracting the Payload from a MIME Message

To extract information from a MIME message, you use services from the `pub.mime` folder to create a MIME object from a MIME message and extract data from it.

### How to Extract the Payload from a MIME Message

The following procedure describes the general steps you take to extract data from a MIME message.

1. **Place the MIME message in the pipeline as an `InputStream`.** For the Integration Server services to work with a MIME message, the message *must* be passed into the pipeline as an `InputStream`. If your solution acquires the MIME message in another form (such as a `String` or a `byte[]`) you must convert it to an `InputStream` before running the MIME services against it.

**Note:** The way in which you acquire a MIME message and put it in the pipeline will depend on your particular solution. You might retrieve it from a back-end system, you might read it from a file, or you might receive it from a custom content handler. Regardless of how you acquire the message, it must be in the form of an `InputStream` to be able to use it with the MIME services.

2. **Convert the MIME message to a MIME object using the `pub.mime:createMimeData` service.** Pass the `InputStream` containing the MIME message to `createMimeData`. This service returns a MIME object called `mimeData` that contains the message's constituent elements (header fields and content). It also returns a set of values indicating whether the enclosed message is encrypted or digitally signed. (For information about extracting information from an encrypted and/or signed MIME message, see ["Extracting the Payload from a Signed MIME Message" on page 46](#) and ["Extracting the Payload from a MIME Message" on page 43](#).)

**Important:** The MIME object that the `createMimeData` service returns is an `IData` object whose contents you can examine during testing and debugging. However, the internal structure of this object is subject to change in future versions of Integration Server. To extract content from a MIME object, *you must always use* the MIME services that Integration Server provides for this purpose. *Do not* explicitly map data from the elements in the MIME object with the pipeline editor.

3. **Extract the payload from the MIME object using the `pub.mime:getBodyPartContent` service.** This service takes as input the MIME object that you created in the previous step 2. If the message contains multiple parts, you can use the `index` or `contentID` parameter to specify which part you want to retrieve, where:
  - `index` is a `String` that specifies the index number (that is, position number) of the part whose content you want to retrieve. (Index 0 is the first part, Index 1 is the second part, and so forth.)

- *contentID* is a String that specifies the value of the content-ID header whose content you want to retrieve. For example, if you wanted to retrieve the content of from the part with the “content-ID: AJ9994388-0500,” you would set *contentID* to “AJ9994388-0500.”

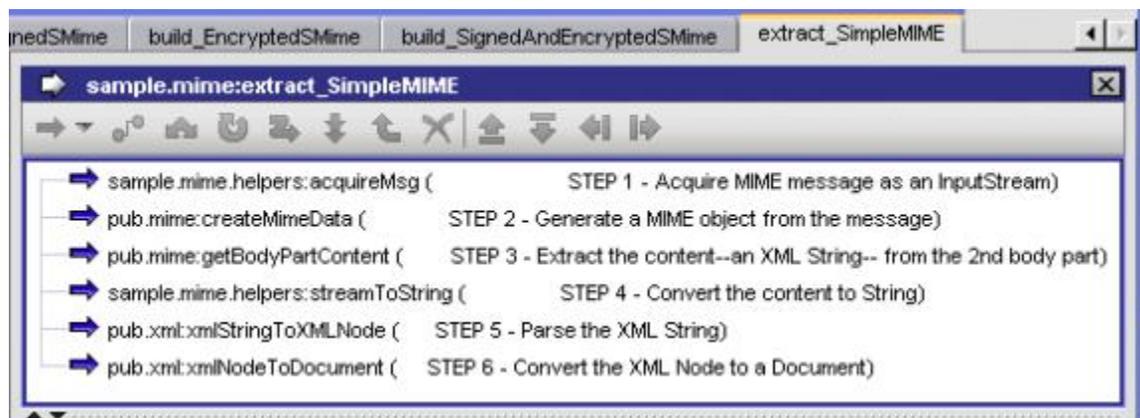

If you do not specify *index* or *contentID*, `getBodyPartContent` returns the content from the first body part in the message.

The content of the requested body part is returned as an `InputStream` named *content*.

## Example—Extracting One Part from a Multipart MIME Message

The following flow service shows how you would extract the content from the second body part in a three-part MIME message. In this example, the message contains an XML document that is extracted, parsed, and put in the pipeline.

### Flow service that extracts content from a single part

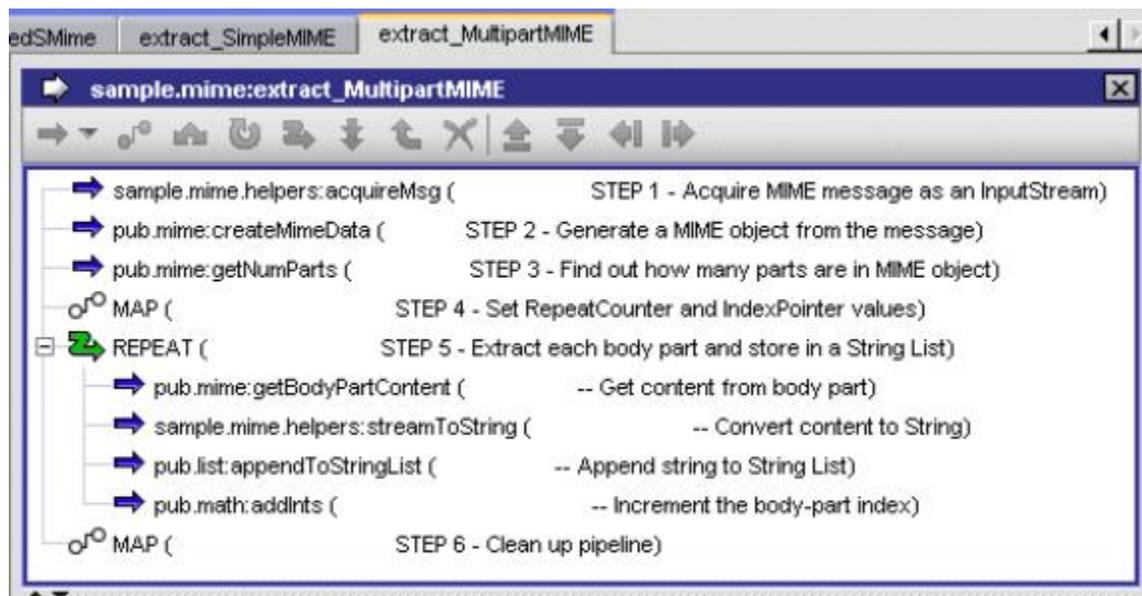

Step	Description
1	This step acquires a MIME message. This example calls a helper service that puts a three-part test message in the pipeline as an <code>InputStream</code> . In a production solution, it is more likely that a MIME message would be passed into the pipeline by a content handler or a back-end system.
2	This step takes the MIME message and creates a MIME object ( <i>mimeData</i> ) containing the message’s headers and content. If you view the pipeline, you will note that the <code>InputStream</code> produced by step 1 is linked to this step’s <i>input</i> variable.
3	This step extracts the payload from the second body part in <i>mimeData</i> . In this example, the <i>index</i> parameter is set to 1 to select the second body part.  This step returns the payload (in this case an XML document) as an <code>InputStream</code> named <i>content</i> .

Step	Description
4	This step converts the XML document in <i>content</i> to a String.
5	This step takes the String containing the XML document and parses it, producing an XML node containing the XML document.
6	This step produces a document (IData object) containing the XML document's elements and values.

## Example—Extracting All Parts from a Multipart MIME Message

The following flow service shows how you might process each part in a multipart MIME message sequentially. This example receives a multipart MIME message containing an unknown number of body parts. After discovering the number of body parts, the example uses a REPEAT block to extract the payload from each part.

Flow service that extracts the content from multiple parts

Step	Description
1	This step acquires a MIME message. This example uses a helper service that generates a three-part MIME message and puts it in the pipeline as an <code>InputStream</code> call <code>envStream</code> . In a production solution, it is more likely that a MIME message would be passed into the pipeline by a content handler or a back-end system.

- | Step | Description   |
|------|---|
| 2    | This step takes the MIME message and creates a MIME object ( <i>mimeData</i> ) containing the message's headers and content. If you view the pipeline, you will note that the <i>InputStream</i> produced by step 1 is linked to this step's <i>input</i> variable. |
| 3    | This step inspects the <i>mimeData</i> object and returns the number of body parts (in this case 3) in a String called <i>numParts</i> .  |
| 4    | This step sets the following variables that are used by the REPEAT block:   |

Variable	Value	Purpose
RepeatCounter	<i>numParts</i> -1	Sets the counter that specifies the number of times the REPEAT block needs to re-execute. Since a REPEAT block always executes once, this counter is set to one number less than the total number of body parts in the message.
<i>PartIndex</i>	0	Initializes the pointer that is used to step through the body parts in this message.

- 5 This REPEAT block does the following for each body part in *mimeData*:
1. Extracts the content
  2. Converts the retrieved content to a String
  3. Appends that String to a String list
- The last step in the block increments *PartIndex*. If you view the pipeline, you will see that this variable is linked to the *index* parameter for the *getBodyPartContent* service.
- 6 This step drops unnecessary variables, leaving only the populated String list in the pipeline.

## Extracting the Payload from a Signed MIME Message

When you pass a signed S/MIME message to *createMimeData*, it returns an empty MIME object because it cannot parse signed messages. To extract data from a signed message, you must process the message with *pub.smime:processSignedData*. This service reads an *InputStream* containing a signed message, verifies the signature, and returns a MIME object containing the message's constituent elements.

**Important:** A signer's certificate is authenticated against the set of trusted certificates in the Integration Server truststore. If your site will receive signed messages, you must collect the certificates of CAs that you trust and add them to the truststore. For information about the Integration Server truststore and obtaining CA certificates, see *webMethods Integration Server Administrator's Guide*.

## How Do You Know Whether the Message Is Signed?

If your solution always receives signed messages, you can simply pass those messages to `processSignedData` when you receive them. However, if your solution receives both signed and unsigned messages, you will need to “test” the message to see whether or not it is signed and pass only signed messages to the `processSignedData` service.

To discover whether a MIME message is signed, pass it to the `createMimeData` service and check the status of the `signed` variable afterwards. If the value of `signed` is “true,” you must pass the message to `processSignedData` for signature verification.

## Working with InputStreams

To work with signed (and encrypted) messages successfully, you need to understand something about the behavior of an `InputStream`. `InputStream`s are transient forms of data in a flow service. When a service reads an `InputStream`, it immediately discards the data within it. This means that once you process a MIME message with `createMimeData`, the message no longer exists in the original `InputStream` object.

This poses a problem if, after running `createMimeData` on the `InputStream`, you discover that it contains a signed or encrypted message. Because the original `InputStream` has been emptied, it cannot be passed to the signature-verification or decryption services. To solve this problem, `createMimeData` returns a copy of the original `InputStream` in an output variable called `stream`. This is the variable you pass to `processSignedData` if, after processing the original message with `createMimeData`, you discover that it is signed.

## What Happens when the Signature is Processed?

When `processSignedData` processes a signed message, it does the following:

- It verifies the digital signature using the signer's public key.
- It compares the signer's certificate chain to the certificates in Integration Server's truststore to determine whether the credentials are authentic and trustworthy.
- It extracts the message from the S/MIME message stream, parses it, and puts it in the pipeline as a MIME object called `mimeData`.

## Error Codes and Messages

If an error prevents the signature from being verified (for example, if the signer's certificate cannot be read or the signature itself is found to be invalid) `processSignedData` sets the `verify` flag to false and reports the cause of the failure in `errorCode` and `errorMessage` as follows:

<u><code>errorCode</code></u>	<u><code>errorMessage</code></u>	<u>Signature could not be verified because...</u>
1	Invalid signer certificate file information.	The signer's certificate could not be read. The variable containing the certificate chain is not an array object.
2	Certificate at index ' <i>i</i> ' is not in recognizable format.	The signer's certificate could not be read. The data at position <i>i</i> in the certificate chain does not appear to be a certificate.
3	Invalid certificate input at index ' <i>i</i> '.	The signer's certificate could not be read. The data at position <i>i</i> in the certificate chain is not a byte[ ].
4	Signature cannot be verified.	The signature was invalid. Either the supplied certificate does not belong to the original signer or a message integrity violation has occurred.

If `processSignedData` is able to verify the signature, but is not able to authenticate the certificate of the signer (that is, the certificate could not be confirmed to be from a trusted source), the `verify` flag will be true and the `errorCode` and `errorMessage` values will be set as follows.

<u><code>errorCode</code></u>	<u><code>errorMessage</code></u>	<u>Certificate could not be authenticated because...</u>
5	Expired certificate chain.	One or more certificates in the supplied chain is expired.
6	Error in certificate chain.	The certificate chain is incomplete or invalid. For example, the certificate for an intermediate CA may be missing from the chain.
7	Untrusted certificate.	None of the CAs in the chain are trusted by this server. None of the certificates could

<i>errorCode</i>	<i>errorMessage</i>	Certificate could not be authenticated because...
		be matched to a certificate in the server's truststore.

If `processSignedData` is able to verify the signature and authenticate the signer's certificate, it does not return `errorCode` or `errorMessage`.

**Note:** Regardless of whether `processSignedData` is able to verify the signature or authenticate the certificate, it always returns a MIME object containing the parsed message.

## How to Extract the Payload from a Signed S/MIME Message

The following procedure describes the general steps you take to extract data from a signed S/MIME message.

1. **If you do not know whether the message is signed, pass it to the `pub.mime:createMimeData` service.** Afterwards, test the state of the *signed* output parameter. If its value is "true," proceed to the next step 2. Otherwise, check whether the message is encrypted and process it as described in ["Extracting the Payload from an Encrypted MIME Message" on page 51](#). If the message is neither signed nor encrypted, process it as an ordinary MIME message as described in ["Extracting the Payload from a MIME Message" on page 43](#).
2. **Pass the message to the `pub.smime:processSignedData` service to verify the signature.** If the signer's certificate chain is included in the signature, you do not need to give this service anything other than the `InputStream` containing the MIME message. If the signer's certificate chain is not embedded in the signature, you must supply it (this assumes that the signer has given you a certificate chain at some point).

Keep in mind that if the message was passed to `createMimeData` before this step, the original `InputStream` will be empty. In this case, you must pass the *stream* output variable produced by `createMimeData` to the `processSignedData` service.

3. **Test the verify flag and perform error processing as necessary.** If the signature cannot be verified, *verify* will be false. Your service should contain logic to detect this condition and react in a prescribed way. For example, it might send the message to an administrator for a manual inspection or record the event in a log file.

**Note:** Depending on the nature of the messages your service receives, you may want to test the *encrypted* output variable after processing a signature. This will tell you whether the message had been encrypted before it was signed. If *encrypted* is "true," you will need to decrypt the message in *stream*. For procedures, see ["Extracting the Payload from an Encrypted MIME Message" on page 51](#).

4. **Extract the payload from the MIME object using the `pub.mime:getBodyPartContent` service.** If the enclosed message is not encrypted, `processSignedData` returns a MIME object that contains the message's constituent elements (header fields and content). At this point, you can use

`getBodyPartContent` to retrieve the content from the MIME object. For information about using `getBodyPartContent`, see ["Extracting the Payload from a MIME Message" on page 43](#).

## Example—Extracting Content from a Signed S/MIME Message

The following flow service extracts the payload from a signed MIME message.

To run this example, you must have a private key, the associated certificate, and the certificate of the CA that signed it. These credentials are needed by the helper service, `sample.smime.helpers:acquireSignedMsg`, which generates the signed test message used in this example. You will need to edit the first step in the helper service to specify the location of these files on your system.

This service assumes that the signature contains the signer's certificate chain, so you do not need to supply a certificate chain at run time.

### Flow service that extracts the content from a signed MIME message

Step	Description
------	-------------

- |   |  |
|---|--|
| 1 | This step acquires an <code>InputStream</code> containing a signed MIME message. This example uses a helper service to produce a test message. In a production solution, it is more likely that a MIME message would be passed into the pipeline by a content handler or a back-end system.  |
| 2 | This step takes the <code>InputStream</code> generated in step 1 and processes the signature. If the signature is valid, this step produces a MIME object called <code>mimeData</code> , containing the parsed message. If the signature is invalid, this step returns an empty <code>mimeData</code> object and sets the <code>verify</code> flag to "false." |
| 3 | This step checks whether or not the signature was processed successfully by testing the value of the output variable <code>verify</code> . If <code>verify</code> is "true," this step extracts the payload and converts it to a <code>String</code> . If <code>verify</code> is "false," this step  |

Step	Description
	collects the error information in the pipeline and passes it to an error-logging service.

## Extracting the Payload from an Encrypted MIME Message

When you pass an encrypted S/MIME message to the `createMimeData` service, it returns an empty MIME object, because it cannot parse encrypted messages. To extract data from an encrypted message, you must decrypt the message with `pub.smime.keystore:processEncryptedData`. This service reads an `InputStream` that contains an encrypted message, decrypts it using a private key pointed by the keystore alias and key alias that you supply, and returns a MIME object containing the message's constituent elements.

### How Do You Know Whether the Message Is Encrypted?

If your solution always receives encrypted messages, you can simply pass those messages to `processEncryptedData` when you receive them. However, if your solution receives both encrypted and clear-text messages, you will need to “test” a message to see whether or not it is encrypted, and pass only encrypted messages to the `processEncryptedData` service.

To discover whether a MIME message is encrypted, pass it to the `createMimeData` service and check the status of the `encrypted` variable afterwards. If the value of `encrypted` is “true,” you must pass the message to `processEncryptedData` to be decrypted.

**Note:** When you process an `InputStream` with `createMimeData`, that `InputStream` is emptied and is no longer available to other services. For this reason, `createMimeData` returns a copy of the original message stream in the output variable called `stream`. You pass this variable to `processEncryptedData` if the original `InputStream` has been emptied by `createMimeData`. For additional information about `InputStreams`, see ["Working with InputStreams" on page 47](#).

### How to Extract the Payload from an Encrypted S/MIME Message

The following procedure describes the general steps you take to extract data from an encrypted S/MIME message.

1. **If you do not know whether the message is encrypted, pass it to the `pub.mime:createMimeData` service.** Afterwards, test the state of the `encrypted` output parameter. If its value is “true,” proceed to the next step 2. Otherwise, test the `signed` variable to see whether the message is signed and process it as described in ["Extracting the Payload from a Signed MIME Message" on page 46](#). If the message is neither signed nor encrypted, process it as an ordinary MIME message as described in ["Extracting the Payload from a MIME Message" on page 43](#).

2. **Pass the message to the `pub.smime.keystore:processEncryptedData` to be decrypted.** You must pass three input parameters to this service: the `InputStream` containing the encrypted MIME message, the keystore alias that points to the recipient's keystore, and the key alias that identifies the recipient's private key in the keystore.

Keep in mind that if the message was passed to `createMimeData` prior to this step, the original `InputStream` will be empty. In this case, you must pass the `stream` output variable produced by `createMimeData` to the `processEncryptedData` service.

**Note:** Depending on the nature of the messages your service receives, you may want to test the `signed` output variable after decrypting the message. This will tell you whether the message had been signed prior to being encrypted. If `signed` is "true," you will need to verify the signature of the message in `stream`. For procedures, see ["Extracting the Payload from a Signed MIME Message" on page 46.](#)

3. **Extract the payload from the MIME object using the `pub.mime:getBodyPartContent` service.** If the decrypted message is not signed, the MIME object returned by `processEncryptedData` will contain the message's constituent elements. You use `getBodyPartContent` to retrieve the content from this MIME object. For information about using `getBodyPartContent`, see ["Extracting the Payload from a MIME Message" on page 43.](#)

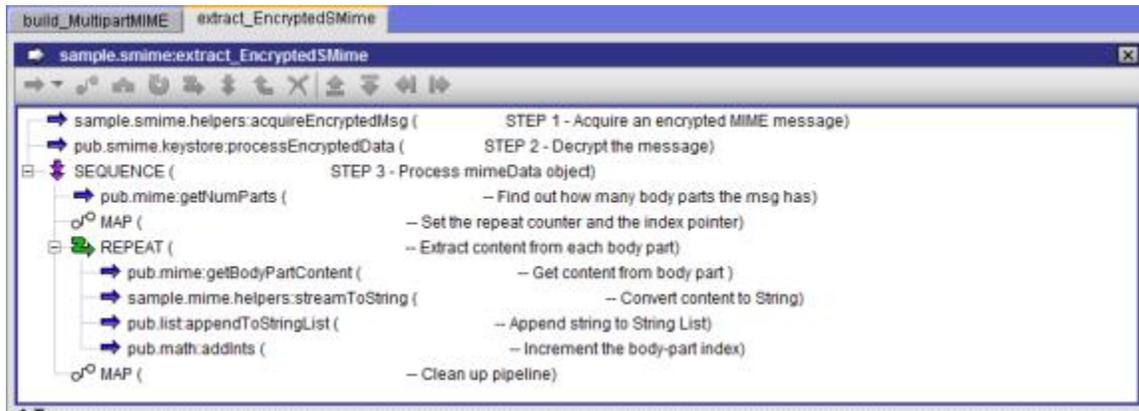

## Example—Extracting Content from an Encrypted S/MIME Message

To run this example, you must provide the keystore alias and key alias for the recipient's private key. Some of these credentials are needed by the helper service, `sample.smime.helpers:acquireEncryptedMsg`, which generates the test message used in this example. You will need to edit the first step in the helper service to specify the location of these files on your system.

When you run this service from Designer, it will prompt you for the following:

Input Parameter	Description
<code>recipientsKeystoreAlias</code>	<b>String</b> Alias of the recipient's keystore.
<code>recipientsKeyAlias</code>	<b>String</b> Alias of the private key in the recipient's keystore.

### Flow service that extracts the content from an encrypted MIME message

Step	Description
------	-------------

- |   |   |
|---|---|
| 1 | This step acquires an <code>InputStream</code> containing an encrypted multipart MIME message. This example uses a helper service to produce the test message. In a production solution, it is more likely that a MIME message would be passed into the pipeline by a content handler or a back-end system. |
| 2 | This step takes the <code>InputStream</code> from step 1 and decrypts the message. It produces a MIME object ( <i>mimeData</i> ) that contains the decrypted message's constituent elements (header fields and content).  |
| 3 | This step extracts each body part from <i>mimeData</i> and appends it to a String list.   |

## Extracting Data from a Signed and Encrypted MIME Message

If your solution receives messages that are signed and/or encrypted, your flow service must test each incoming message and process it appropriately.

### Example—Extracting Content from a Signed and Encrypted S/MIME Message

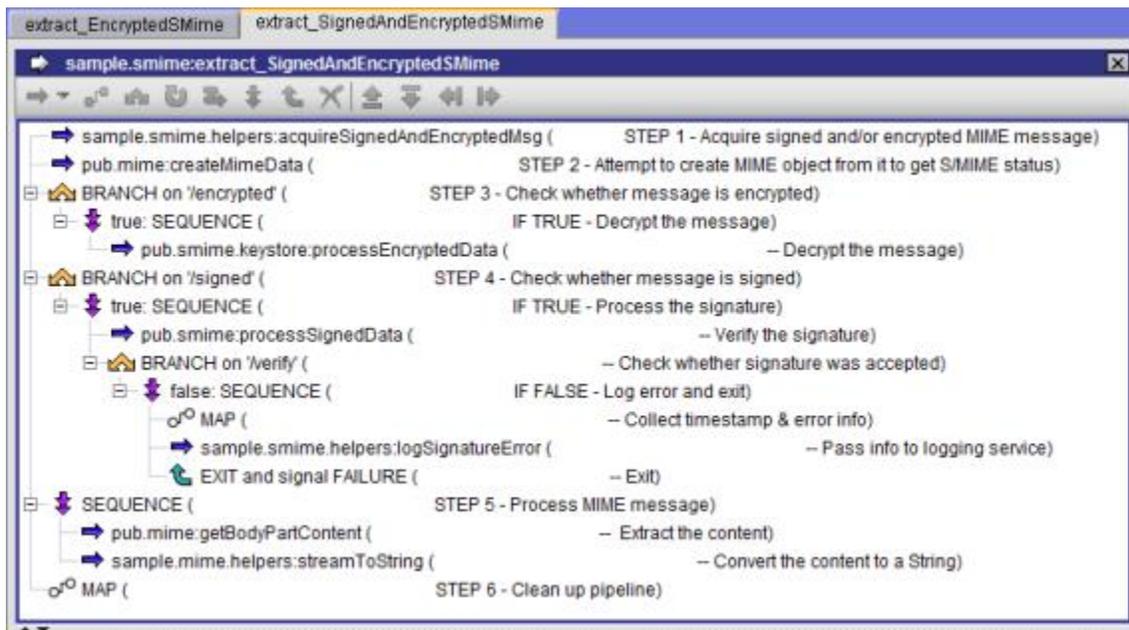

The following flow service extracts data from MIME and S/MIME messages.

To run this example, you must provide the keystore alias and key alias for the recipient's private key. Some of these credentials are needed by the helper service, `sample.smime.helpers.acquireSignedAndEncryptedMsg`, which generates the test message used in this example. You will need to edit the first step in the helper service to specify the location of these files on your system.

When you run this service from Designer, it will prompt you for the following:

Input Parameter	Description
<i>recipientsKeystoreAlias</i>	<b>String</b> Alias of the recipient's keystore.
<i>recipientsKeyAlias</i>	<b>String</b> Alias of the private key in the recipient's keystore.

### Flow service that extracts the content from a signed and/or encrypted MIME message

Step	Description
1	This step acquires an <code>InputStream</code> containing a signed and encrypted MIME message. This example uses a helper service to produce the test message. In a production solution, it is more likely that a MIME message would be passed into the pipeline by a content handler or a back-end system.
2	This step attempts to create a MIME object from the <code>InputStream</code> produced in step 1.
3	This step tests the <i>encrypted</i> flag to see whether the message is encrypted. If it is, it obtains the credentials needed to decrypt the message and passes those credentials and the message to the <code>processEncryptedData</code> service. Note that the <i>stream</i> output variable is linked to the <code>SMimeEnvStream</code> input parameter, because the original <code>InputStream</code> from step 1 was emptied by step 2.  Note that if <i>encrypted</i> is “false,” execution falls through to step 4.

<b>Step</b>	<b>Description</b>
<b>4</b>	<p>This step tests the <i>signed</i> flag to see whether the message is signed. If it is, it passes the message to the <code>processSignedData</code> service. Note that the <i>stream</i> output variable is linked to the <code>SMimeEnvStream</code> input parameter, because the original <code>InputStream</code> from step 1 was emptied in step 2. (When a message is decrypted in step 3, the <code>processEncryptedData</code> service produces the <i>stream</i> used by this step.)</p> <p>Note that if <i>signed</i> is “false,” execution falls through to step 5.</p>
<b>5</b>	<p>This step extracts the data from the <i>mimeData</i> object produced by the preceding steps.</p>
